Title : Securing the Soils of Karabakh Steppe with  
Nutrient Elements.  
Orig Pub : Sotz. s. kh. Azerbaydzhana, 1957, No. 6,  
28-30

Abstract : Meadow soils, located in Karabakh Steppe  
(Azerbaydzhan), contain 213.4-246.7 t/ha of  
organic substances and up to 15.3 of total N,  
7.9 t of total P and 5.5 t of exchangeable  
K. The gray-brown soils contain, respecti-  
vely, 75.8-84.4, 6.8-12.4, 7.1; of total K  
44-53.3 t/ha. In comparison with meadow soils,  
they contain five times more of easily hydro-

Abstract : lyzable N. The sierozems are poor in total N  
(5.6 t/ha), but contain sufficient reserves  
of easily-hydrolyzable N. Reserves of assi-  
milated phosphoric acid are not large (0.077  
t/ha). According to reserves of total K, they  
exceed all other soils, but in comparison with  
exchangeable K, they occupy last place. These

Hydration property of serum protein in diffuse hepatitis and nephritis. I. V. Dzhavakhishvili (Med. Inst., Tbilisi). *Terap. Arkh.* 28, No. 8, 18-23 (1956). In Rotkin's disease, cirrhosis of the liver, and the splenomegalic syndrome the hydration energy of the protein mols. and their stability in soln. is increased. There is a return to normal with clinical improvement. In diffuse nephritis the hydration energy is decreased, the stability in solns. is less, with a return to normal when the patient improves. Nephritis with azotemia is similar to hepatic diseases in the behavior of the protein mols. *Mel*

TITLE: Petrographic Investigation of Structural Rammed Earth  
(Opyt petrograficheskogo issledovaniya stroyeniya  
udarno-uplotnennykh strukturnykh gruntov)

PERIODICAL: Tr. Gruz. n.-i. in-ta gidrotekhn. i melior. 1956,  
Vol 4(17), pp 244-255

ABSTRACT: The author gives the results of petrographic investigations of the change in structure of soils after their consolidation by impact. The investigations were carried out on earth of the first (soil?) level of the Samgora test sector in the original deposit and after consolidation by two and by 12 blows. The consolidation was produced by impacts with various impulses (50, 75 and 100 g.sec/sq cm) and at various

Card 1/5

Petrographic Investigation (Cont.)

moisture contents (20, 26 and 30 percent). The soils were described as assorted, humus-containing, argillaceous mixtures of the gray-wacke type with a kaolinite-hydromicaceous dispersed fraction and a loose granular structure. Specimens were studied under the microscope in parallel thin polished and unpolished sections oriented horizontally and vertically with relation to the impact. In evaluating the degree of soil consolidation under the microscope, principal attention was devoted to the character of the structure, to the location of the aggregates with respect to each other and their internal structure, to the percentage of silt grains per unit of area occupied by the soil, and to the distribution and character of cracks and pores. The investigations showed that these soils are composed basically of two types of aggregates--the coarse and the fine. The coarse aggregates with diameters of 1 mm to 3 mm are, for the most part, isometric and can be broken into finer contiguous aggregates with diameters of 0.3 mm to 0.4 mm. Sand-silt grains are few in number and are generally located between the fine aggregates.

Card 2/5

15-57-8-11598

Petrographic Investigation (Cont.)

The microtexture of the coarse aggregates is often irregular, sometimes concentric and rarely microstratified. All these argilaceous soil types are intersected by cracks with a transverse section of 0.4 mm to 0.8 mm, oriented in various directions between the large aggregates. The total microporosity (relation of the total surface area to the area occupied by the soil) produced by the large and average-size cracks is equal to 12 percent. The large aggregates, in turn, are intersected by fine cracks running between them and between the small aggregates. These fine cracks comprise 1.8 percent of the soil. Soil without cracks amount to 1.5 percent. After consolidation, the character and the quantitative relations of porosity changed. Following the impact impulses of 75 g·sec/sq cm, no large cracks could be found, and medium size cracks were traced only in specimens consolidated at 20 percent moisture content. The total microporosity in all cases was reduced to 2.1 to 3.2 percent and lower. After impacts of the same impulse, the total porosity was from 6 to 9 percent. With an impact impulse of 50 g·sec/sq cm, all

Card 3/5

Petrographic Investigation (Cont.)

forms of porosity were preserved and the total porosity was 2.6 to 5.3 percent. The cracks in the soil after consolidation were oriented directionally; they were frequently mutually perpendicular and were developed along the horizontal and vertical directions with relation to the impact. At the time of consolidation, cracks in soil at different moisture contents became filled with different materials. Thus, in consolidation of soil at 26 percent moisture content, the cracks became filled with silty material, while at 20 percent moisture content, they became filled with pelitic material. Attempts to determine the material with which the cracks were filled at 30 percent moisture content were unsuccessful. It was established that the character of the structure (consolidation of the aggregates) changed with the moisture content, impulse and number of impacts, and that the soil often acquired a horizontal stratification caused by the linear deposit of hydromica scales or by the stratified distribution of the silty or pelitic microlaminae. These experiments represent a visual petrographic method for investigating the changes

in the internal structure of soil subjected to impact consolidation.

TITLE: EPR and optical absorption in neutron-irradiated lithium fluoride crystals

SOURCE: AN GruzSSR. Institut fiziki. Elektronnyye i ionnyye protsessy v tverdykh telakh, v. 2, 1965, 19-26

TOPIC TAGS: lithium fluoride, EPR spectrum, halide optic material, alkali halide, neutron irradiation, crystal dislocation phenomenon

ABSTRACT: Test samples of LiF were cut from monocrystalline melts of natural material and irradiated in the atomic reactor of the Physics Institute, AN GruzSSR. The radiation energy of  $1.9 \cdot 10^{15}$  to  $2.9 \cdot 10^{16}$  was selected because alkali halide crystals are known to change their optical and mechanical characteristics significantly at these energies. EPR spectra were studied with standard radiospectrometers and with a doubly modulated magnetic field. The field was calibrated from the proton resonance signal and measurements were made at 77 and 290K. The EPR spectrum approximates a Gaussian curve, and the width of the EPR absorption line depends on crystal orientation to the magnetic field as well as on the radiation dosage. The coloration curve of the

TITLE: Measurement of the EPR spectrum of teflon at helium temperatures

PERIODICAL: Optika i spektroskopiya, v.12, no.6, 1962, 789-791

TEXT: For obtaining the EPR spectrum of teflon at the temperatures of liquid helium and hydrogen a superheterodyne spectrometer previously described was used together with a specially constructed cryostat. The cryostat consists of the usual double Dewar vessel with heat shields but designed so that the resonator with the sample is contained in a brass cylinder, 40 mm diameter, maintained at the temperature of liquid helium (or hydrogen) in the required magnetic field. The Dewar vessel is capable of containing liquid helium for 12 to 14 hours. Spectra were obtained from samples of teflon exposed in the Institute of Physics reactor to a mixture of n-,  $\gamma$ -radiation with a flux of thermal neutrons of  $4.2 \times 10^{12}$  n/cm<sup>2</sup> sec for 2 hours. The general dose was about 30 megarads. These spectra consist of a single line with anisotropic broadening attributed to the

peroxide radical of teflon. The value of the g-factor at 4.2°K is  $2.013 \pm 0.003$  compared with  $2.011 \pm 0.003$  at 80°K and  $2.022 \pm 0.003$  at room temperature. At 4.2°K and 80°K the shape of the line is almost the same. These results agree well with those obtained by other authors. Measurements were also made on samples of teflon with polymer molecules predominantly orientated in a given direction. Symmetrical lines are observed at helium temperatures, the form of which is not dependent on the orientation of the sample w.r.t. the external magnetic field. The g-factor is  $2.011 \pm 0.003$  and the line width about 40 Oe. When the power input is increased the lines are distorted by saturation effects. The spin-lattice relaxation time is estimated to be about  $10^{-3}$  to  $10^{-4}$  sec. There are 4 figures.

212 Neurology Feb 59

cord and of the motor and sensory areas of the brain in 16 dogs following section of the right sciatic nerve, over a period of from 12 days to 6 months. After the nerve section, retrograde degeneration spread and reached the trophic centre (i.e. the corresponding segment of the grey matter in the cord) of the damaged nerve fibres within 1.5 to 6 months. The changes in the capillary network of the grey matter of the cord consisted in considerable widening and a marked increase in tortuosity of the capillaries. These changes were more evident in the anterior horns and the intermediate regions than in the posterior horns of the spinal cord. The nerve section has less influence on the anglo-architectonics of the motor and sensory areas of the brain than on the capillaries of the cord, and was characterized mainly by atrophic changes.
